

# Cigarette Smoking and Outcomes after Allogeneic Hematopoietic Stem Cell Transplantation

Betty T. Tran,<sup>1,2</sup> Abigail Halperin,<sup>3</sup> Jason W. Chien<sup>1,2</sup>

Abnormal lung function is a known risk factor for poor outcomes in the allogeneic hematopoietic stem cell transplantation (HSCT) population, although the specific causes of these abnormalities have not been well explored. There is limited data on the effect of cigarette smoking on transplantation outcomes. We conducted a retrospective observational cohort study of 845 consecutive patients age  $\geq 18$  years who underwent allogeneic HSCT at the Seattle Cancer Care Alliance/Fred Hutchinson Cancer Research Center. Smoking exposure was defined by quit time, smoking status (never, former, and current), and  $\log_2$ -transformed pack-years. The main outcomes were time to respiratory failure within 100 days of transplantation, relapse, and nonrelapse mortality. In multivariable analyses, a 2-fold increase in pack-years smoked was associated with an increased risk of early respiratory failure (hazard ratio [HR] 1.33, 95% confidence interval [CI] 1.09 to 1.64,  $P = .006$ ). This association was observed independent of pretransplantation lung function. A 2-fold increase in pack-years smoked was associated with an increased risk of relapse, but this finding was not statistically significant (HR 1.16, 95% CI 0.92-1.46,  $P = .21$ ). An association was not observed between cigarette smoking and nonrelapse mortality. Cigarette smoking is associated with an increased risk of respiratory failure and relapse within 100 days of allogeneic HSCT. The association with respiratory failure is mediated in part by abnormal lung function before transplantation and likely through other mechanisms as well. Given the adverse effects associated with cigarette smoking before transplantation, future studies should focus on obtaining accurate smoking histories, tracking prospective changes in smoking status, and assessing the benefits of tobacco cessation on outcomes in this population.

## INTRODUCTION

Allogeneic hematopoietic stem cell transplantation (HSCT) has become standard therapy to treat a variety of malignant and other hematologic diseases, with over 20,000 allogeneic transplantations performed annually worldwide [1]. Despite its widespread use, transplantation-related mortality and morbidity remain high. The 100-day mortality rate for allogeneic transplantations ranges from 10% to 40% [2]. In addition, 15% to 40% of all allogeneic HSCT recipients require

intensive care admission after transplantation [2,3]. Pulmonary complications account for most of the life-threatening conditions that develop posttransplantation, and traditionally, are classified as early or late depending on whether they occur before or after day 100.

Prior studies have suggested that abnormal pretransplant pulmonary function tests (PFTs) increase the risk of complications, including early respiratory failure and mortality [4-7]. Causes for abnormal pretransplantation lung function, however, have not been well explored. Cigarette smoking is known to be a primary cause of abnormal PFTs [8,9], and previous studies have reported that 14% to 62% of transplantation candidates have a former or current history of smoking [10-13]. Cigarette smoking, therefore, may account for some of the abnormal PFTs observed before transplantation, but there are limited data on the direct effects of cigarette smoking on early pulmonary complications, relapse, and mortality posttransplantation. Marks et al. [12] reported that "high-dose" smoking, defined by  $\geq 10$  pack-year history and smoking  $\geq 1$  pack per day, was associated with an increased risk of treatment-related mortality and disease relapse. Some studies have

reported an increased risk of early pulmonary complications among smokers, whereas others have not demonstrated such associations [11,13]. In general, these studies have been limited by small numbers of patients or have focused on only certain transplantation populations. Furthermore, despite growing evidence that cigarette smoking impairs immune function, exacerbates cancer treatment-related toxicities, and increases risk of recurrence and secondary malignancies, few clinical oncology studies collect information on smoking history unless the malignancy is primarily smoking related [14-17]. Given these limitations, we conducted a retrospective observational cohort study to assess the relationship between pretransplantation cigarette smoking and early respiratory failure, relapse, and posttransplantation nonrelapse mortality (NRM) among adult allogeneic HSCT recipients.

## METHODS

### Patient Selection

All adult patients (age  $\geq 18$  years) who received an allogeneic HSCT at Fred Hutchinson Cancer Research Center between June 20, 2005, and June 30, 2009, were eligible for the study ( $n = 846$ ). On June 20, 2005, routine tracking of smoking history began during pretransplantation pulmonary function testing.

### Cigarette Smoking

Cigarette smoking was the primary exposure. Smoking history was obtained via self-report during pretransplantation pulmonary function testing and categorized as never, former, or current. For this study, we defined a former smoker as an individual who quit smoking for at least 1 year before the interview. Patients who were currently smoking or had quit for  $<1$  year before the interview were considered current smokers. Smoking dose was defined in pack-years (number of cigarettes smoked per day/20 multiplied by years smoked) and  $\log_2$ -transformed to achieve a normal distribution.

### Outcomes Assessment

The primary outcomes were respiratory failure within 100 days, disease relapse, and NRM. Early respiratory failure was defined as mechanical ventilation for a nonelective reason within 100 days after transplantation. Because the majority of our patients are discharged from our center after 100 days, this time period provides the most complete and accurate respiratory failure data [7]. For patients who had multiple episodes of respiratory failure within 100 days, only the time to the first respiratory failure episode was analyzed. NRM was defined as mortality without evidence of disease relapse.

## Covariates

Data were collected on patient demographics, including age, gender, and race. Disease risk was defined as low, intermediate, or high risk for mortality as described by Parimon and colleagues [18]. Low-risk diseases include chronic myelogenous leukemia (CML) in chronic phase, refractory anemia, and aplastic anemia. Intermediate-risk diseases include CML in accelerated phase or chronic phase after blast phase, acute leukemia or lymphoma in remission, refractory anemia with excess blasts, and chronic lymphocytic leukemia. High-risk diseases include chronic myelogenous leukemia in blast phase, acute leukemia, or lymphoma in relapse, myeloma, solid tumor, and nonhematologic diseases. Pertinent data were also collected to calculate a Pretransplant Assessment of Mortality (PAM) score as previously described [18].

Stem cell sources were classified as bone marrow, peripheral blood stem cell (PBSC), cord blood, or a combination of bone marrow and PBSC. Donor match status was determined according to donor-recipient human leukocyte antigen (HLA) compatibility. Conditioning regimens were categorized as myeloablative or nonmyeloablative. Myeloablative regimens were further grouped according to the dose of total-body irradiation used: none,  $\leq 12$  Gy, or  $>12$  Gy. Cytomegalovirus (CMV) serologic status was assessed in both recipient and donor. Acute graft-versus-host disease (aGVHD) was graded I-IV, and categorized as “no” (grades 0-II) or “yes” (grades III-V) based on stages of organ involvement using standard criteria [19,20]. Chronic GVHD (cGVHD) was defined by the National Institutes of Health (NIH) 2005 criteria [21].

Pulmonary function testing was obtained routinely before transplantation and again approximately 80 to 120 days posttransplantation. All pulmonary function tests were performed at the Fred Hutchinson Cancer Research Center according to American Thoracic Society guidelines [22]. All pulmonary function values, except the ratio of forced expiratory volume in 1 second ( $FEV_1$ ) to forced vital capacity (FVC), were expressed as a percentage of predicted values according to published equations [23,24], unless otherwise specified. Diffusing capacity for carbon monoxide ( $DL_{CO}$ ) measurements were corrected for hemoglobin levels obtained at the closest time to the  $DL_{CO}$  measurement [25].

## Statistical Methods

All statistical analyses were performed using STATA 11.0 (StataCorp, College Station, TX). Baseline variables were compared between smoking groups using Pearson chi-square testing or  $t$  tests for continuous variables. Time-to-event analyses were conducted using Cox proportional hazards regression models to estimate the hazard ratios (HRs) for associations between pretransplantation smoking and transplantation outcomes. Huber-White standard errors were used to

relax traditional proportional hazards assumptions. In secondary analyses, we used linear regression to examine the association between smoking dose and days 80 to 120 pulmonary function. The multivariable model included smoking status as a categorical variable and  $\log_2$ -transformed pack-years. We decided a priori to also include age, gender, and conditioning regimen as potential confounders. Additional covariates, including patient race, disease risk, CMV status, stem cell source, donor HLA match, PAM score, and aGVHD and cGVHD modeled as time-varying covariates, were evaluated independently in the models and included in the final adjusted models based on likelihood ratio testing. Measures of pulmonary function were then added to the multivariable model. Only FEV<sub>1</sub> and DL<sub>CO</sub> were included in these models because of the high correlation among FEV<sub>1</sub>, FVC, total lung capacity (TLC), and the lack of correlation between DL<sub>CO</sub> and the other pulmonary function parameters [7]. Two-sided *P* values <.05 were considered statistically significant.

Data for each patient were censored at the time of the event of interest, death, or date of last contact, whichever came first, with the exception of analyses involving early respiratory failure, where patients were censored at 100 days if they did not have the outcome or died. In analyses involving nonrelapse mortality and relapse, these outcomes were considered competing events and censored accordingly. Data for 1 patient was censored at 83 days at the time of a second transplantation.

## RESULTS

From July 20, 2005, to June 30, 2009, 846 patients underwent allogeneic HSCT. One patient was excluded for missing smoking data. Clinical characteristics are summarized in Table 1. There were 230 former smokers (27%) and 85 current smokers (10%). The overall median number of pack-years smoked was 10 (interquartile range [IQR] 4-25). The median number of days before transplantation that a smoking history was obtained was 24 days (IQR 20-35 days). The median age was 58 years (IQR 51-63 years) in former smokers and 46 years (IQR 32-57 years) in current smokers compared with 50 years (IQR 38-59 years) in never smokers. This is slightly older than in previous studies and reflects the trend of increasing numbers of allogeneic transplantations among individuals older than 50 years of age [10-13,26]. Former smokers were more likely to receive a nonmyeloablative conditioning regimen, consistent with older age in this group. Although the majority of transplantation patients at our institution undergo bronchoscopy for evaluation of acute radiographic abnormalities, specific pulmonary infections are difficult to identify in this cohort because the majority of patients are already taking broad-spectrum antibiotic and antifungal therapy before bronchoscopy. Neverthe-

less, there was no significant difference in the rate of bronchoscopies performed in never smokers versus former or current smokers. There were no significant differences with regard to patient gender, ethnicity, underlying disease severity, donor HLA match, CMV status, and stem cell source between the groups.

PFTs, including spirometry and DL<sub>CO</sub>, were obtained on 96% of patients before transplantation. Over 75% of patients in all 3 smoking groups had normal FEV<sub>1</sub>, FVC, and TLC percent predicted values (Table 2). Both former and current smokers had slightly lower FEV<sub>1</sub> and FEV<sub>1</sub>/FVC compared to never smokers. A greater proportion of current smokers had DL<sub>CO</sub> values that were <80%.

## Smoking and Early Respiratory Failure

Early respiratory failure occurred in 32 (6%) never smokers, 14 (6%) former smokers, and 2 (2%) current smokers. The median number of days after transplantation to respiratory failure was 17.5 days (IQR 11-29.5 days). Forty-four of the 48 patients (92%) died after receiving mechanical ventilation. The main reasons for respiratory failure included acute respiratory distress syndrome (ARDS)/acute lung injury (ALI) (*n* = 15, 31%), aspiration/mucositis (*n* = 11, 23%), diffuse alveolar hemorrhage (*n* = 8, 17%), and idiopathic pneumonia syndrome (*n* = 7, 14%), as defined by previous criteria [27-29]. In multivariable analyses adjusting for age, sex, conditioning regimen, smoking status, and aGVHD, smoking dose, defined in pack-years, was associated with a higher risk of early respiratory failure. For each doubling of pack-years, the HR for early respiratory failure increased 33% (95% confidence interval [CI] 1.09 to 1.64, *P* = 0.006) (Figure 1).

Figure 2 shows the projected cumulative incidence curves, using our model for early respiratory failure, with all HSCT predictors being equal except smoking dose. In this projection, we combined former and current smokers into 1 group and compared a never-smoking patient to a smoker with a 20 pack-year history and another smoker with a 40 pack-year history.

To better understand how abnormal pulmonary function may have accounted for the association between pretransplantation smoking and early respiratory failure, we then included pretransplantation pulmonary function in the multivariable model. As expected, the addition of variables for pulmonary function attenuated our HR for early respiratory failure, but an association between the 2-fold increase in pack-years and risk of early respiratory failure remained (HR 1.25, 95% CI 1.02-1.55, *P* = 0.03) (Figure 1).

## Smoking and Relapse

One hundred sixty-two of the patients relapsed, including 105 (20%) never smokers, 42 (18%) former smokers, and 15 (18%) current smokers, with a median

IQR indicates interquartile range; TBI, total-body irradiation; PBSC, peripheral blood stem cell; BM, bone marrow; CMV, cytomegalovirus; GVHD, graft-versus-host disease.

number of days after transplantation to relapse of 103 (IQR 71-239 days). Over three-quarters of those who relapsed (78%) died. In multivariable analyses adjusting for age, gender, conditioning regimen, smoking status, disease risk, donor HLA type, and aGVHD and cGVHD (as time-varying covariates), a 2-fold increase in pack-years was associated with a higher risk of relapse, but this finding was not statistically significant (HR 1.16, 95% CI 0.92 to 1.46,  $P = .21$ ) (Figure 1).

### Smoking and NRM

There were 386 (46%) deaths from all causes in this cohort. Of these, 127 had relapsed, leaving 259 (31%) individuals (156 [37%] never smokers, 79 [42%] former smokers, 24 [34%] current smokers) with NRM. The median number of days after transplantation to NRM was 163 days (IQR 62-298 days). In multivariable analyses adjusting for age, gender,

conditioning regimen, smoking status, donor HLA type, PAM score, stem cell source, and aGVHD and cGVHD, smoking dose was not associated with a higher risk of NRM (HR 0.97, 95% CI 0.85-1.10,  $P = .64$ ) (Figure 1).

### Smoking and Day 100 Pulmonary Function

We performed secondary analyses of the relationship between smoking dose and pulmonary function obtained routinely 80 to 120 days posttransplantation. After adjustment for patient age, gender, conditioning regimen, and smoking status, smoking dose was not significantly associated with changes in FEV<sub>1</sub>, FVC, TLC, or DL<sub>CO</sub> from baseline (data not shown).

### Stratification by Donor Type

Because prior studies have cited differential transplantation outcomes with HLA-identical sibling

**Table 2. Distribution of Pretransplant Pulmonary Function Tests**

transplants versus unrelated matched transplants, we analyzed the association between cigarette smoking and transplantation outcomes separately for these subgroups. After adjustment, there was still an increased risk of early respiratory failure with a 2-fold increase in pack-years in both groups. Patients who received an HLA-identical related transplant had an 83% increased risk of early respiratory failure (95% CI 1.18 to 2.84,  $P = .007$ ) compared with a 46% increased risk among patients receiving an unrelated matched transplant (95% CI 1.02-2.09,  $P = .04$ ) (Table 3). Smoking dose was associated with an increased risk of relapse in patients receiving an unrelated matched transplant (HR 1.44, 95% CI 1.04-2.01,  $P = .03$ ). There was a weak association between pack-years and relapse in related matched donor transplants that was not significant (HR 1.21, 95% CI 0.92-1.60,  $P = .17$ ). Smoking dose was again not associated with NRM when stratified by donor type (Table 3).

## DISCUSSION

The major finding of our study is that lifetime smoking dose is associated with an increased risk of respiratory failure within 100 days of transplant. This relationship appears to be only partially mediated by pretransplant lung function, suggesting that other biological mechanisms may be involved. We did not observe significant effects of smoking on overall re-

lapse or NRM, although the direction of the association between smoking dose and relapse warrants further investigation.

Few studies have examined whether cigarette smoking is a risk factor for poor transplantation outcomes, and those have had conflicting results. Ho et al. [11] found that smoking history, measured by smoking status (never, current, quit >1 year) was not associated with increased risk for early severe pulmonary complications, defined as diffuse alveolar hemorrhage, need for mechanical ventilation, or death from respiratory failure within the first 60 days posttransplantation. In contrast, a study done by Savani and colleagues [13] reported that a history of smoking was associated with a 5-fold increase in the risk of transplantation-related mortality from pulmonary causes. The latter, however, had a smaller cohort ( $n = 146$ ), included patients diagnosed with idiopathic pneumonia syndrome, and followed patients for a median of 3.6 years. The largest study by Marks et al. [12], with 2818 patients who received allogeneic transplants for CML in the first chronic phase, found that the risk of treatment-related mortality was 57% higher among ≥10 pack-year smokers compared with never smokers. In addition, such a smoking history was associated with an increased risk of disease relapse, a finding consistent with a prior study by Chang et al. [10,12]. These findings, however, were observed only in recipients of HLA-identical sibling donor transplants [12].

**Figure 1.** Multivariable adjusted hazards ratios for the association between cigarette smoking and early respiratory failure, relapse, and NRM.

We also found an increased risk of relapse associated with smoking, although mainly among patients receiving an unrelated matched HSCT. These results should be considered preliminary, although in light of studies demonstrating that smoking increases the risk of hematologic malignancies, this may be biologically plausible [30,31]. The >2-fold increase in relapse risk among recipients of unrelated matched donors in our study may be partly attributable to our cohort having a higher underlying disease risk; we included

a variety of underlying diseases that warranted allogeneic transplantation as opposed to the cohorts in the Chang and Marks studies, which focused on CML in a stable phase. Unlike the study by Marks et al., we did not find an association between smoking and NRM, despite observing that 92% of patients who were placed on mechanical ventilation in the first 100 days after transplantation ultimately died. It is

**Figure 2.** Projected cumulative incidence curves for early respiratory failure associated with never smoking versus 20 pack-year smoking history versus 40 pack-year smoking history.

**Table 3. Multivariable Adjusted HRs for the Association between Smoking and Early Respiratory Failure, Relapse, or Nonrelapse Mortality, Stratified by Donor HLA Type**

Outcome	N (%)	HR	95% CI	P value
Related matched donor 307 (36%)				
Early respiratory failure*		1.83	1.18 to 2.84	.007
Relapse†		1.21	0.92 to 1.60	.17
Nonrelapse mortality‡		0.99	0.77 to 1.29	.97

possible that some patients with respiratory failure chose to forego mechanical ventilation before death. Alternatively, it is possible that smoking is not a risk factor for other common causes of non-relapse mortality such as aGVHD or cGVHD and nonpulmonary organ toxicity or failure. There are several possible mechanisms for the association between smoking dose and early respiratory failure. Pretransplantation PFTs are reportedly important predictors of early posttransplantation pulmonary complications and mortality [5-7]. These parameters likely represent markers of previous lung injury and worse health status before transplantation. In addition, cigarette smoking has immunomodulatory effects that have been linked to increased susceptibility to infection. The alveolar macrophages found in the lungs of smokers, for example, have a reduced ability to phagocytose bacteria and are known to secrete lower levels of inflammatory cytokines necessary for up-regulation of host defenses [32,33]. Cigarette smoke may also have independent effects on mucociliary clearance and alterations in surfactant proteins [34-38].

The strengths of our study include a large cohort, availability of detailed smoking history, and availability of PFTs near transplantation. There are, however, important limitations to consider when interpreting our results. First, social desirability, especially before an upcoming transplantation, may have led to underreporting of smoking. Although we do not have reason to believe this bias is differential among those who experienced respiratory failure or died, the effect would tend to bias our HRs toward the null. Second, we could not assess whether smoking was continued or resumed during the posttransplantation period, which may have affected our outcomes. Third, although there are no firm exclusion criteria with regard to PFTs, smoking status, or pulmonary disease for transplantation eligibility at our center, patients with severe pulmonary and other comorbidities may never have made it to transplantation; thus, there could be selection bias. Despite these limitations, the findings that: (1) the vast majority of patients undergoing transplantation have normal lung function, including former and current smokers (Table 2), and (2) an association remains between smoking dose and early respiratory failure independent of lung function, lends credence to our conclusion that cigarette smoking, even in patients without serious comorbidities or compromised lung function, has independent deleterious effects after transplantation.

In summary, our study found a significant association between cigarette smoking and respiratory failure within 100 days of transplantation. This finding appears to be only partially mediated by abnormal lung function before transplantation. Although we found no significant association between smoking and relapse or NRM after allogeneic HSCT, a trend was apparent,

and future prospective studies with longer-term outcomes and ongoing monitoring of smoking status are warranted to explore this issue. We are not suggesting that HSCT should be withheld or delayed in patients with a smoking history in need of transplantation; however, because cigarette smoking identifies individuals at increased risk of early morbidity posttransplantation, they should be counseled accordingly. Given the prevalence of smoking among HSCT cohorts, further studies should focus on tobacco cessation efforts in this patient population. In addition, they should evaluate the potential impact of length of quit time among former smokers and recent quitters on allogeneic transplantation outcomes, as this could identify a window of opportunity for aggressive tobacco cessation interventions. This study also emphasizes the need for routine inclusion of smoking status and a more detailed smoking history both before and after transplantation in future HSCT studies.
